I discuss heavy quarkonium radiative transitions and the related issue of the quarkonium magnetic moment inside effective field theories. Differences in set up and conclusions with respect to typical phenomenological approaches are outlined.

Keywords: Quarkonium, NRQCD, pNRQCD, radiative transitions

Heavy quarkonium radiative transitions have been studied for long time in the framework of phenomenological models^{1–14} (for a recent review see¹⁵). In a typical set up⁷, the starting point is a relativistic Hamiltonian whose dynamical fields are heavy quarks and photons; gluons are integrated out and replaced by a scalar and a vector interaction. The non-relativistic nature of heavy quarkonia is exploited by performing a Foldy–Wouthuysen transformation. Anomalous magnetic moments are added as if the system was made of two particles independently interacting with the external electromagnetic field.

Such an approach, despite phenomenological success, has an obvious limitation: its connection with QCD is unclear. More precisely, while it relies on a systematic (non-relativistic) expansion to describe the electromagnetic interaction of the heavy quarks, it does not describe their strong interaction. As a result, the nature of the binding potential between the two heavy quarks and of the couplings of the heavy quarks with the electromagnetic field remains elusive. In particular, one may wonder if the heavy quarkonium anomalous magnetic moment gets contributions from the interaction of the heavy quarks in the bound state and if, in the non-relativistic expansion, the many couplings between the heavy quarks and the electromagnetic field, allowed by the symmetries of QCD, really orga-

nize as if they were generated by only two relativistic form factors (i.e. the scalar and vector interactions). Finally, the lack of a systematic expansion reflects in the fact that model-dependent determinations are affected by unknown uncertainties.

In the modern framework of non-relativistic effective field theories (EFTs)^{16–20}, one takes advantage of the small heavy quark velocity v to organize calculations of heavy quarkonium observables so that theoretical uncertainties can be evaluated and systematically reduced. Applied to radiative transitions, the EFT approach provides eventually definite answers to the above questions²¹. This is done through the following step.

First, one has to identify the relevant scales in the system. These are the heavy quark mass m , the typical momentum transfer in the bound state, which is of order mv , and the typical binding energy, which is of order mv^2 . The momentum of the emitted photon, k_γ , is of order mv^2 for transitions between different radial levels (like magnetic-dipole hindered transitions) and usually of order mv^4 for transitions between levels with the same principal quantum number (like magnetic-dipole allowed transitions). Since the typical distance between the two heavy quarks is $r \sim 1/(mv)$, then $k_\gamma r \ll 1$ and the external electromagnetic field can be multipole expanded (at least for transitions between not too far away levels). We neglect virtual photons, whose contributions are suppressed by α . In QCD, it is also crucial to establish the size of these scales with respect to the typical hadronic scale Λ_{QCD} . By definition of heavy quark: $m \gg \Lambda_{\text{QCD}}$; however, $mv \gg \Lambda_{\text{QCD}}$ holds possibly only for the lowest quarkonium resonances, while $mv \sim \Lambda_{\text{QCD}}$ holds for the others. In the first case, called weakly coupled, the scale mv may be treated in perturbation theory (in this case $v \sim \alpha_s$), in the last one, called strongly coupled, at the scale mv one cannot rely on an expansion in α_s and non-perturbative techniques have to be used.

In order to construct an EFT suitable to describe heavy quarkonium transitions, we do not need to resolve scales larger than or of the same order as the soft scale mv . These scales may be integrated out from the EFT. The relevant degrees of freedom differ in the weakly and in the strongly coupled case. If $mv \gg \Lambda_{\text{QCD}}$ these are singlet, S, and octet, O, quarkonium fields, gluons of energy and momentum mv^2 or Λ_{QCD} (sometimes also called ultrasoft) and photons. If $mv \sim \Lambda_{\text{QCD}}$, at scales lower than mv colour confinement sets in and the relevant degrees of freedom are singlet quarkonium fields (all gluonic excitations between heavy quarks develop a mass gap of order Λ_{QCD} with respect to the lowest state and are integrated out) and photons. Fields scale in accordance to the lowest, still dynamical,

energy scales, defining in this way the power counting of the EFT.

The EFT Lagrangian has the following form:

$$\begin{aligned}
\mathcal{L} = & -\frac{1}{4}F_{\mu\nu}^{\text{em}}F^{\mu\nu\text{em}} + \int d^3r \text{Tr} \left\{ S^\dagger \left(i\partial_0 - \frac{\mathbf{p}^2}{m} - V_s \right) S \right\} \\
& \left[-\frac{1}{4}F_{\mu\nu}^a F^{\mu\nu a} + \int d^3r \text{Tr} \left\{ O^\dagger \left(iD_0 - \frac{\mathbf{p}^2}{m} - V_o \right) O \right\} \right. \\
& + \int d^3r V_A \text{Tr} \{ O^\dagger \mathbf{r} \cdot g\mathbf{E} S + S^\dagger \mathbf{r} \cdot g\mathbf{E} O \} \\
& + \left. \int d^3r V_B \frac{1}{2} \text{Tr} \{ O^\dagger \mathbf{r} \cdot g\mathbf{E} O + O^\dagger O \mathbf{r} \cdot g\mathbf{E} \} + \dots \right]_{\text{weak coupling only}} \\
& + \mathcal{L}_\gamma,
\end{aligned} \tag{1}$$

where $\mathcal{L}_\gamma$ is the part of the Lagrangian that describes the interaction with the electromagnetic field. In the case of magnetic-dipole transitions, the relevant terms in $\mathcal{L}_\gamma$ up to relative order v^2 are:

$$\begin{aligned}
\mathcal{L}_\gamma = & \int d^3r \text{Tr} \left\{ V_A^{\text{em}} S^\dagger \mathbf{r} \cdot e\mathbf{E}^{\text{em}} S + \frac{1}{2m} V_1 \{ S^\dagger, \boldsymbol{\sigma} \cdot e\mathbf{B}^{\text{em}} \} S \right. \\
& + \left[\frac{1}{2m} V_1 \{ O^\dagger, \boldsymbol{\sigma} \cdot e\mathbf{B}^{\text{em}} \} O \right]_{\text{weak coupling only}} \\
& + \frac{1}{4m^2} \frac{V_2}{r} \{ S^\dagger, \boldsymbol{\sigma} \cdot [\hat{\mathbf{r}} \times (\hat{\mathbf{r}} \times e\mathbf{B}^{\text{em}})] \} S + \frac{1}{4m^2} \frac{V_3}{r} \{ S^\dagger, \boldsymbol{\sigma} \cdot e\mathbf{B}^{\text{em}} \} S \\
& + \left. \frac{1}{4m^3} V_4 \{ S^\dagger, \boldsymbol{\sigma} \cdot e\mathbf{B}^{\text{em}} \} \nabla_r^2 S + \dots \right\},
\end{aligned} \tag{2}$$

where e is the electric charge of the heavy quark. The Wilson coefficients V_s , V_o , V_A , V_B , V_A^{em} , V_i are in general functions of r and have to be determined by matching amplitudes calculated in the EFT with amplitudes calculated in QCD. The matching may be performed order by order in α_s in the weak-coupling case, but has to be performed non-perturbatively in the strong-coupling one. In both situations, the matching can be done in two steps: the first one consists of integrating out hard modes of energy of the order of the heavy quark mass, the second one of integrating out soft modes of energy of the order of mv . The Wilson coefficients of the EFT will then have the factorized form: (hard) $\times$ (soft). For determinations of V_s , V_o , which are the singlet and octet potentials, and V_A , V_B we refer to²⁰ and references therein. The coefficients V_A^{em} and V_i have been studied in²¹. In the following, we summarize the main conclusions.

The coefficient V_1 may be interpreted as the heavy quarkonium magnetic moment. Its hard part is simply the sum of the heavy quark magnetic moments: $1 + 2\alpha_s/(3\pi) + \dots$. Moreover, it can be shown that, in the $SU(3)_{\text{flavour}}$ limit, to all orders in the strong-coupling constant, V_1 does not get soft contributions. The argument is somewhat similar to the factorization of the QCD corrections in $b \rightarrow u e^- \bar{\nu}_e$, which fixes the coefficient in the effective Lagrangian $\mathcal{L}_{\text{eff}} = -4G_F/\sqrt{2} V_{ub} \bar{e}_L \gamma_\mu \nu_L \bar{u}_L \gamma^\mu b_L$ to be 1 to all orders in α_s (see, for example,²²). This leads to the conclusion that the heavy quarkonium magnetic moment, if defined as the Wilson coefficient V_1 , is just the sum of the heavy quark magnetic moments. Therefore, its anomalous part is small and positive and does not get any large low-energy and, in particular, non-perturbative contribution. This is consistent with a recent lattice determination²³. Note that a large negative heavy quarkonium anomalous magnetic moment has been often advocated in potential models to accommodate the results with the data.

Reparametrization and Poincaré invariance^{24,25} protect the coefficients V_2 and V_3 . To all orders in perturbation theory and non-perturbatively it holds that $V_2 = r^2 V_s^{(0)}/2$ ($V_s^{(0)}$ is the singlet static potential) and $V_3 = 0$. Since an effective scalar interaction would contribute to V_3 , we conclude that such an interaction is not dynamically generated in QCD for magnetic-dipole transitions. Again, a scalar interaction is often employed in potential models.

The coefficient V_A^{em} is 1 up to possible corrections of order α_s^2 . In general, the coefficients of the operators of order $1/m^3$ are not protected by any symmetry. V_4 is 1 plus $\mathcal{O}(\alpha_s)$ corrections. In the weak-coupling case, this is the only $1/m^3$ operator needed to describe magnetic-dipole transitions at relative order v^2 . In the strong coupling regime, more terms are, in principle, necessary. Since $\alpha_s(1/r) \sim 1$ is no longer a suppression factor, more amplitudes shall contribute to the matching. These amplitudes will be encoded in the matching coefficients of the EFT in the form of static Wilson loop amplitudes with field strength insertions of the same kind as those that appear in the QCD potential at order $1/m^2$ ²⁶. Also, they may induce new operators in the EFT. A non-perturbative derivation of the EFT Lagrangian coupled to the electromagnetic field at order $1/m^3$ has not been worked out yet; note that to be of phenomenological impact such a calculation needs to be supplemented by lattice calculations of the relevant Wilson loop amplitudes. Since most of the potential model calculations rely on Lagrangians of the type of Eq. (2), we emphasize that, once cleaned up of the scalar interaction, they are suitable to describe the relativistic corrections for ra-

diative transitions between weakly-coupled quarkonia ($mv^2 \gtrsim \Lambda_{\text{QCD}}$) only. This is a rather severe constraint since most of the radiative transitions (e.g. magnetic dipole hindered, electric dipole, ...) involve higher excited quarkonium states, which may be difficult to accommodate as Coulombic bound states.

At present, allowed magnetic-dipole transitions between the quarkonium lowest states are those most reliably described in QCD. Moreover, it has been shown in²¹ that for these processes, non-perturbative contributions mediated by quarkonium octet states and ultrasoft gluons cancel at relative order v^2 . Therefore, at relative order v^2 , transitions like $J/\psi \rightarrow \eta_c \gamma$ and $\Upsilon(1S) \rightarrow \eta_b \gamma$ are completely accessible in perturbation theory. An explicit calculation gives:

$$\Gamma(J/\psi \rightarrow \eta_c \gamma) = (1.5 \pm 1.0) \text{ keV}, \quad (3)$$

$$\Gamma(\Upsilon(1S) \rightarrow \eta_b \gamma) = \left(\frac{k_\gamma}{39 \text{ MeV}} \right)^3 (2.50 \pm 0.25) \text{ eV}. \quad (4)$$

The error in Eq. (3) accounts for the large uncertainties coming from higher-order corrections; we recall that corrections of order $k_\gamma^3 v^2/m^2$ affect the leading-order result by about 50%. Uncertainties may be reduced by higher-order calculations. The value given in Eq. (3) is consistent with the present experimental one²⁷. This means that assuming the ground-state charmonium to be a weakly-coupled bound state leads to relativistic corrections to the transition width of the right sign and size. The decay width $\Gamma(\Upsilon(1S) \rightarrow \eta_b \gamma)$ depends on the η_b mass, which is unknown. The quoted value corresponds to a η_b mass of about 9421 MeV.

We conclude with few possible developments of the work discussed here. For magnetic-dipole transitions between higher resonances, the completion of the non-perturbative matching of the relevant operators in the EFT at order $1/m^3$ will be needed, possibly integrated by lattice calculations of the relevant Wilson-loop amplitudes. For magnetic-dipole hindered transitions of the type $\Upsilon(3S) \rightarrow \eta_b \gamma$, since the momentum of the emitted photon is comparable with the typical momentum transfer in the bound state, one cannot rely on the multipole expansion of the external electromagnetic field. In this case, one may, in principle, exploit the fact that the typical momentum transfer inside the η_b is much larger than that one inside the $\Upsilon(3S)$. A suitable treatment has not been developed yet. For electric-dipole transitions, much of the study still remains to be done. In the weak-coupling regime, octet contributions may not vanish; they can be worked out as in the case of the magnetic-dipole transitions. However, most of the electric-

dipole transitions may need to be treated in a strong-coupling framework.

Acknowledgements

I thank Nora Brambilla and Yu Jia for an enjoyable collaboration on the work presented here. I acknowledge the financial support obtained inside the Italian MIUR program “incentivazione alla mobilità di studiosi stranieri e italiani residenti all’estero”.
